Processing of lexical stress cues by young children

ARTICLE INFO

ABSTRACT

Although infants learn an impressive amount about their native-language phonological system by the end of the first year of life, after the first year children still have much to learn about how acoustic dimensions cue linguistic categories in fluent speech. The current study investigated what children have learned about how the acoustic dimension of pitch indicates the location of the stressed syllable in familiar words. Preschoolers (2.5- to 5-year-olds) and adults were tested on their ability to use lexical-stress cues to identify familiar words. Both age groups saw pictures of a bunny and a banana and heard versions of "bunny" and "banana" in which stress either was indicated normally with convergent cues (pitch, duration, amplitude, and vowel quality) or was manipulated such that only pitch differentiated the words' initial syllables. Adults ($n = 48$) used both the convergent cues and the isolated pitch cue to identify the target words as they unfolded. Children ($n = 206$) used the convergent stress cues but not pitch alone in identifying words. We discuss potential reasons for children's difficulty in exploiting isolated pitch cues to stress despite children's early sensitivity to pitch in language. These findings contribute to a view in which phonological development progresses toward the adult state well past infancy.

Introduction

Infants begin learning their native language during the first year, passing a series of milestones on their path toward mastery in interpreting the speech signal. They lose discrimination of some non-na-

tive consonant and vowel contrasts (Bosch & Sebastián-Gallés, 2003; Polka & Werker, 1994; Werker & Tees, 1984) and improve discrimination of subtle native contrasts (Kuhl et al., 2006; Narayan, Werker, & Beddor, 2010), which enables them to focus on the sound contrasts that their native language uses to differentiate words. They begin to use their language's prosodic properties to guide word finding (e.g., Friederici, Friedrich, & Christophe, 2007; Nazzi, Jusczyk, & Johnson, 2000; see also Curtin, Mintz, & Christiansen, 2005; Höhle, Bijeljac-Babic, Herold, Weissenborn, & Nazzi, 2009; Jusczyk, Cutler, & Redanz, 1993). In addition, they derive increasingly detailed knowledge of which sounds or syllables tend to go together (Jusczyk, Friederici, Wessels, Svenkerud, & Jusczyk, 1993; Jusczyk, Luce, & Charles-Luce, 1994).

Yet toddlers are still immature in their interpretation of the speech signal. For example, 1-year-olds do not consistently interpret phonological distinctions as indicating lexical distinctions even for contrasts they readily discriminate (Apfelbaum & McMurray, 2011; Fennell & Werker, 2004; Rost & McMurray, 2009; Stager & Werker, 1997; Swingley & Aslin, 2007; Werker & Curtin, 2005). They are also more open-minded than older children about what can constitute a word, apparently accepting gestures and mechanical sounds (Namy, 2001; Namy & Waxman, 1998; Woodward & Hoyne, 1999). Even older children's perception of speech sounds does not align fully with adult models in some phonetic details (e.g., Mayo & Turk, 2005). Thus, although children's (implicit) knowledge of their language's speech sounds implies significant capacities for analysis of regularities in the speech signal, the accomplishments of the first year are just the first steps in learning to interpret spoken language.

To fluently learn and recognize native-language words, children not only must apply their native sound contrasts but also must disregard, at least at the word level, acoustic variation that their language does *not* use contrastively. But in doing so learners cannot simply discard this sort of variation because it is often relevant at other levels of linguistic structure. For example, vowel duration in English is not a primary cue to vowel identity, but it partially cues speech rate and the voicing of the following consonant (Dietrich, Swingley, & Werker, 2007; van der Feest & Swingley, 2011) and, therefore, should not be ignored. The need to attend to non-segmental information also implies that sensitivity to statistical modes in phonetic distributions is unlikely to be sufficient alone as a learning mechanism that can lead to proper interpretation of duration or pitch movement. Children need not only segmental categories but also interpretive models that assign appropriate communicative roles to phonetic variations.

A number of studies have shown children's ability to insulate lexical interpretations from phonetic variations irrelevant to lexical identity. For example, within the first year, infants improve at recognizing words despite non-phonemic changes in the talker's voice (Houston & Jusczyk, 2000), affect (Singh, Morgan, & White, 2004), and fundamental frequency, perceived as pitch (Singh, White, & Morgan, 2008). English-learning 18-month-olds do not treat large differences in vowel duration as contrastive even when given distributional evidence to the contrary (Dietrich et al., 2007). In the case of pitch, Quam and Swingley (2010) demonstrated that by 2.5 years of age, when English-learning children were taught a new word that was consistently uttered with one pitch contour, they recognized the word just as well when it was given a very different contour, suggesting that the children did not spontaneously treat pitch contour as a crucial component of a new word. Children appear to rule out pitch contour as lexically relevant in English sometime between 18 and 24 months of age (Singh, Hui, Chan, & Golinkoff, 2014).

Note that in all of these cases, word recognition is tested and the "right" answer (at least for English learners) requires indifference to the tested nonlexical variable, be it pitch contour, talker's voice, or talker's emotional state. There are relatively few tests of very young children's appreciation of the *significance* of these phonetic variables in English (but see Creel, 2012). So, taking the case of pitch, although even toddlers have some correct intuitions about what pitch is *not* used for in English, it is less clear what young children think pitch *is* used for in English.

For example, it seems that it is not until roughly 4 years of age that children begin to exploit pitch cues to a talker's emotions as adults do (Quam & Swingley, 2012) even when pitch indicates emotions such as "happy" and "sad"—emotions that children talk about before 2.5 years of age (Fenson et al., 1994). This delay in pitch interpretation is surprising given infants' early attention to the pitch characteristics of infant-directed speech (IDS; e.g., Fernald, 1985, 1992; Katz, Cohn, & Moore, 1996). One

possible explanation for the delay could be variability in how underlying representations (happy/sad emotions) manifest in surface forms (realizations of pitch cues). The consistency of the relationship between underlying representations and surface forms appears to affect the acquisition trajectory of phonetic features, including pitch contours. For example, the tone patterns of words appear to be learned more quickly in lexical-tone languages such as Mandarin than in grammatical-tone languages such as Sesotho, where contextual "tone sandhi" effects are pervasive and children appear to learn tone patterns item by item (Demuth, 1995). Within Japanese, a pitch-accent language, the variable realization of the phrase-initial rising contour in adult speech appears to account for children's delayed acquisition of this pattern relative to the more consistently realized falling contour (Ota, 2003). Similarly, inconsistency in how pitch indicates the talker's emotions could slow children's learning of these cues (Quam & Swingley, 2012).

The current study investigated a case in which pitch serves a different linguistic function in English—to indicate the stressed syllable in a word. In English, polysyllabic words each contain one syllable with primary lexical stress. Which syllable this is varies from word to word; for example, *table* is trochaic with stress in the first syllable, whereas *persist* is iambic with stress in the second syllable. Lexical stress in English is indicated by four acoustic cues. One is the pitch pattern; when a word has discourse focus or occurs in a prosodically prominent position (e.g., at the end of the utterance), its stressed syllable attracts a pitch accent, typically a pitch peak (Beckman & Edwards, 1994; Hayes, 1995). Stressed syllables in English also tend to be longer in duration and louder than unstressed syllables. Finally, in English, vowel quality is an additional cue to stress; unstressed syllables tend to contain the vowel schwa, whereas stressed syllables vary more in their vowel quality, generally being less centralized in the vowel space (Fry, 1958; Lieberman, 1960). Because the precise use and weighting of these cues differ across languages (Berinstein, 1979; Bertinetto, 1980), children must learn the cue weightings and realizations for their language.

Here, we asked whether children and adults can exploit stress patterns to efficiently recognize words that differ in first-syllable stress (*BUnny* vs. *baNAna*) and whether the pitch component of lexical stress is important in their determination of whether a syllable is stressed. Participants were tested in a restricted (but common) linguistic context in which the stressed syllable reliably contains a pitch peak (i.e., in sentences such as "Look at the BUnny/baNAna"). Because the context demands realization of the pitch cue to lexical stress as a pitch peak, pitch here is relevant to lexical differentiation.

Both age groups were tested in two conditions. In the *convergent-cues* condition, participants heard words in which pitch, amplitude, duration, and vowel quality all converged to indicate the location of the stressed syllable, just as they ordinarily do in English in this intonational/pragmatic context. Children might be expected to exploit these convergent cues to stress in word recognition given infants' early attentiveness to the stress properties of their language (Friederici et al., 2007) and evidence that early word learners encode stress in their word representations (Curtin, 2010) and can learn minimal stress pairs (Curtin, 2009). On the other hand, children might not use stress effectively given its relatively low functional load compared with, for example, lexical tone in Mandarin Chinese (Cooper, Cutler, & Wales, 2002; Cutler, Dahan, & van Donselaar, 1997), pitch accent in Japanese (Shibata & Shibata, 1990, cited in Sekiguchi & Nakajima, 1999), or even lexical stress in Spanish and Dutch (Hochberg, 1988; Cooper et al., 2002). Even so, we expected that children would indeed exploit the words' stress patterns in differentiating the test words.

In the *pitch-only* condition, participants heard words in which only isolated pitch cues indicated the location of stress. This condition speaks to the question of whether preschool children can flexibly adapt their cue weights to capitalize on the locally informative cue. Given infants' early sensitivity to pitch patterns in language (Fernald, 1985, 1992; Katz et al., 1996), we might predict that children would exploit isolated pitch cues. However, even if children make use of convergent stress cues, there are two reasons to think they might not use pitch alone.

First, children's cue weights may differ from those of adults. Children sometimes over-rely on the most reliable or accessible cue to the exclusion of others. In one example from word segmentation, 7.5-month-olds over-relied on the tendency for words to begin with a stressed syllable, missegmenting *guitar is* as the strong–weak nonword *taris* (Jusczyk, Houston, & Newsome, 1999; see also Houston, Santelmann, & Jusczyk, 2004). At 15 months of age, children also appear to over-rely on the most

salient or reliable acoustic cue to vowel contrasts (the first formant, F1), causing them to fail to discriminate vowel pairs that do not differ primarily in F1 (Curtin, Fennell, & Escudero, 2009). Children may overweight a particular cue because they find it easier to attend to due to either non-adult-like general auditory processing (Mayo & Turk, 2005) or a non-adult-like phonetic system (Nittrouer, 1996; Nittrouer & Lowenstein, 2007). Among the cues to stress, pitch may be less reliable than the others because of its use in signaling other linguistic features such as intonational phrasing and sentential focus. Children might also need multiple cues to a category. Seidl (2007; see also Seidl & Cristià, 2008) found that even though pitch is a necessary cue for infants' clause boundary segmentation, infants are not able to exploit pitch alone to segment clauses but instead need two convergent cues.

Second, children might fail to use pitch as a cue in isolation because of difficulty in flexibly adjusting perceptual weights to capitalize on the locally informative cue. Children exhibit more difficulty than adults in adjusting their phonetic cue weights to compensate for effects of contextual variation such as noise and talker variability (e.g., Hazan & Barrett, 2000; Nittrouer, Miller, Crowther, & Manhart, 2000). Although naturalistic lexical stress is indicated with four convergent cues, in the pitch-only condition listeners could best succeed by adjusting their cue weights to down-weight amplitude, duration, and vowel quality cues relative to pitch. Thus, difficulty in flexibly adjusting cue weights could prevent children from capitalizing on isolated pitch cues in our task.

Given that we might predict late development of the ability to exploit either convergent or isolated pitch cues to lexical stress, we tested children at a broad range of ages: 2.5 through 5 years. This enabled us to investigate whether developmental change occurs across the preschool years in children's ability to exploit stress cues during word recognition. Before testing children, in Experiment 1 we tested a group of adults in both conditions to confirm the manipulation and provide a quantitative assessment of the mature state, particularly with respect to interpretation of the isolated pitch cue.

Experiment 1

We tested 48 adults' recognition of familiar words under two between-participants conditions. In the *convergent-cues* condition, all cues jointly indicated stress. In the *pitch-only* condition, an isolated pitch cue indicated the stressed syllable and all other stress cues were neutralized.

Method

Participants

We included 48 adults (20 women and 28 men) in the analysis, all native speakers of English. All but 2 participants were undergraduates or very recent university graduates, assumed to be between 18 and 23 years of age, recruited primarily through a pool of students in introductory psychology courses. An additional 8 adults participated but were excluded for not being native English speakers (*n* = 6), for equipment failure (*n* = 1), or because the adult's glasses interfered with the eye-tracking (*n* = 1). Because it was likely that adults' responses to isolated pitch cues to stress would be less marked than their responses to convergent stress cues, we tested twice as many participants in the pitch-only condition (32) as in the convergent-cues condition (16).

Apparatus and procedure

We used a language-guided looking procedure to investigate whether adults could exploit convergent versus isolated pitch cues to lexical stress during recognition of familiar words. Because adults participated in essentially the same experiment as children in Experiment 2, experimental trials included only the words/objects *bunny* and *banana* and the auditory stimuli were presented in a child-directed voice. To make this experience seem less odd, adult participants were told before the study that they would be helping to calibrate an experiment designed for young children.

Experimental (bunny/banana) and filler (other familiar word) trials alternated. There were 16 trials of each of these types, making 32 trials in total. In each trial, two pictures appeared on the computer screen. After 2 s, recorded sentences, referring to one of the two pictures, played from speakers on both sides of the screen. Of the 16 experimental trials, there were 4 each of correctly stressed "BUnny"

trials (e.g., "Look at the BUnny"), misstressed "buNNY" trials, correctly stressed "baNAna" trials, and misstressed "BAnana" trials; these four target words were intermixed throughout the experiment. Eight attention-getting videos (e.g., an expanding and contracting star; brightly colored shapes moving around) were evenly spaced throughout, a manipulation used for both age groups but intended for maintaining children's attention in Experiment 2. For adults, there were also 4 filler trials (not eye-tracked) presented between each of the coded trials, so that adults saw 5 trials for every 1 trial children saw. These extra filler trials were intended to render the purpose of the experiment less obvious to adults. Because of these extra trials, the adult experiment was approximately 25 min long.

We used the EyeLink eye-tracking system to automatically code participants' eye movements. The eye-tracker was an EyeLink CL (SR Research), with an average accuracy of 0.5° and a sampling rate (from one eye) of 500 Hz. The EyeLink eye-event detection system is based on an internal heuristic saccade detector. A blink is defined as a period of saccade-detector activity with the pupil data missing for three or more samples in a sequence. A fixation event is defined as any period that is not a blink or saccade.

The eye-tracking camera was mounted to the bottom of a 34.7×26.0-cm LCD computer screen. Before the experiment, we calibrated the eye-tracker to the participant. First, a round sticker with a black-and-white target symbol on it was placed on the participant's forehead just above one of the eyebrows. Then, the experimenter, viewing a live video of the participant's face on the computer monitor, checked whether the eye-tracker had located the target symbol and the participant's pupil and corneal reflection (CR). The eye-tracker used the locations of the target symbol, the pupil, and the corneal reflection to compute the location of the participant's fixations to the screen. Once the target and pupil/CR were identified, the experimenter began the automated 5-point calibration procedure, which involved drawing the participant's gaze to the four corners of the screen and the center in turn using a bulls-eye pattern. Once the calibration and validation were completed satisfactorily, the experiment began. During the experiment, if the eye-tracker lost the location of the pupil/CR, the participant was recalibrated between trials.

Auditory stimuli

Experimental trials used the word pair "bunny" and "banana" for four reasons. First, the words differ in their stress patterns; "bunny" has a stressed first syllable, whereas "banana" has an unstressed first syllable (and a stressed second syllable). Second, the vowel in the first syllable of "bunny" (IPA: /ʌ/) is acoustically similar to schwa (IPA: /ə/), making it easier for us to neutralize the vowel-quality contrast between stressed and unstressed first syllables so as to isolate the pitch cue in the pitch-only condition. Third, both bunnies and bananas are readily picturable. Finally, "bunny" and "banana" constitute the only word pair in most 2-year-olds' vocabularies that fit all three of these criteria.[1] We restricted ourselves to a word pair of this sort rather than simply misstressing words with unmatched partners because previous eye-tracking work with 3-year-olds (de Bree, van Alphen, Fikkert, & Wijnen, 2008) did not show sensitivity to misstressings of iambic words in an unmatched-pair design. In principle, a paired design would be expected to be particularly sensitive because, for example, "buNNY" with an unstressed first syllable not only fails to match *bunny* but also initially provides a good match to *banana*.

Convergent-cues condition. For the convergent-cues condition, the first author produced stimuli in which she allowed all four cues to stress to covary between the two versions of each word. This meant that the first syllable of "BAnana" and "BUnny," in addition to containing a pitch peak, differed in three other ways from the first syllables of "baNAna" and "buNNY." It was longer in duration, higher in amplitude (the mean amplitude of the whole word was normalized to 70 dB, but relative differences between the syllables were maintained), and contained a /ʌ/ vowel rather than schwa (see Fig. 1, top; only one of the two tokens is depicted for each stimulus). We used two tokens of each word (e.g., two "BUnny" tokens); this was partly to reduce boredom in the child version (Experiment 2) and also to

---

[1] Pilot testing also included the pair "button"/"balloon", but the L-coloring of the first vowel in "balloon" eliminated any ambiguity between the first syllables of the words.
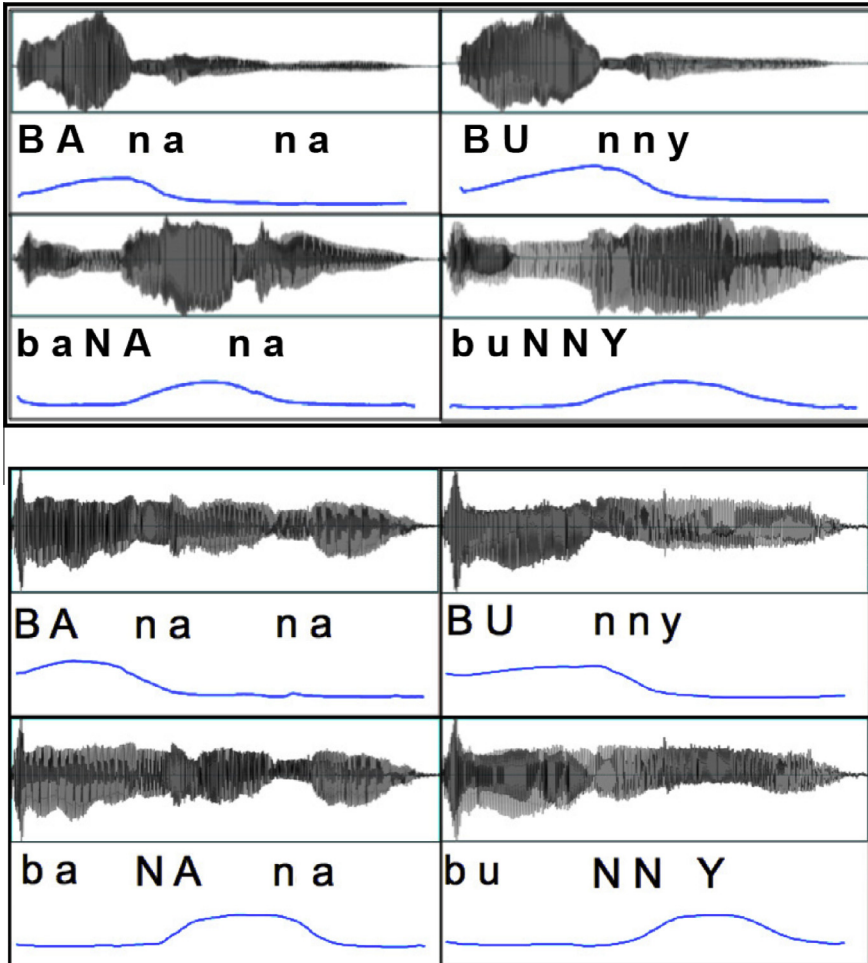

Fig. 1. Waveforms and pitch tracks for one of the two tokens of each of the auditory stimuli used in the convergent-cues condition (top) and for the stimuli used in the pitch-only condition (bottom).

reduce the likelihood that participants could memorize the acoustic values of particular stimuli (e.g., the precise pitch values of "BAnana" vs. "BUnny") to anticipate which word they were hearing.

Pitch-only condition. To test English-speaking adults' and children's ability to exploit the pitch cue to stress, for the pitch-only condition we used Praat *pitch resynthesis* (Boersma & Weenink, 2008) to isolate the pitch cue to the stress contrast between "bunny" and "banana," holding the other three cues—amplitude, duration, and vowel quality—constant (see Fig. 1, bottom). In simple declarative or "wh-" question contexts such as the sentences we used ("Look at the bunny/banana." and "Where's the bunny/banana?"), the stressed syllable of a word with utterance focus is indicated with a pitch peak during the stressed syllable (Hayes, 1995). In these simple sentence contexts, therefore, a word with a stressed first syllable will have an earlier pitch peak than a word with a stressed second syllable.

To isolate the pitch cue, the first author first recorded tokens of each word with stress on the first or second syllable (e.g., BUnny and buNNY) and also a "neutrally stressed" version of each word, in which she attempted to produce comparable values for amplitude, duration, and vowel quality in the first and second syllables, so that stress was not clearly on either syllable (but note that it is not possible

to produce fully "neutral" stress, so the long first-syllable duration may have suggested first-syllable stress when listening incrementally). Mean amplitude between syllables of the "neutrally stressed" tokens was equalized using the "shape volume" function in the acoustic editing software Goldwave.

Next, we superimposed the pitch contour from each of the stressed versions onto the neutrally stressed tokens, using Praat pitch resynthesis (Boersma & Weenink, 2008; see Streeter, 1978, for a similar procedure). Thus, the stimuli presented to listeners were two versions of the same recorded tokens, with superimposed pitch patterns taken from either trochaic or iambic recordings. This method enabled us to ensure that the two versions of *bunny* and of *banana* differed, to the extent possible, in only their pitch contours. Acoustic measurements for stimuli in both conditions are summarized in Table 1. (Note that the pitch-resynthesis process isolates pitch as much as possible, but some small differences in amplitude and spectral content, which can be seen in Table 1, are unavoidable if stimuli are to sound like speech). Because of the complexity of creating these resynthesized stimuli (e.g., to maximize the naturalness of the resynthesis process, syllable durations needed to be similar among the trochaic, iambic, and "neutrally" stressed original recordings), only one token of each experimental stimulus (e.g., "BUnny") was used and was spliced into the two carrier phrases "Look at the [BUnny]." and "Where is the [BUnny]?" Waveforms and pitch tracks for the resulting stimuli are shown in Fig. 1 (bottom).

Visual stimuli

Visual stimuli were color photographs on gray backgrounds. There were two different *banana* photos and two different *bunny* photos (see examples in Fig. 2) as well as two versions of each of the filler pictures. In pilot testing, participants (especially children) had a strong bias to fixate the *bunny* in bunny/banana trials, so for the experiments reported here we reduced the size and contrast of the *bunny* photos and increased the size and brightness of the *banana* photos. This reduced (but did not eliminate) children's baseline (before target word) preference for the *bunny* object.

Data reduction

The 500-Hz output files of the EyeLink system were converted to ASCII format and condensed into target- and competitor-fixation proportions in 50-ms time bins using custom Python scripts created

Table 1
Acoustic measurements for the first and second syllables of each target word used in the convergent-cues condition (averaged over the two tokens of each word) and the pitch-only condition.

	Pitch mean (*SD*) (Hz)	Pitch max (Hz)	Intensity (dB)	Duration (s)	F1/F2 (Hz)
Convergent cues–first syllable					
baNAna	201.5 (10.1)	235.8	68.1	0.26	626.4/1751.5
BAnana	371.6 (49.9)	424.3	75.5	0.40	975.9/1420.5
BUnny	374.4 (52.6)	431.6	74.5	0.40	920.5/1610.5
buNNY	195.4 (4.9)	204.6	69.3	0.17	601.4/1748.6
Convergent cues–second syllable					
baNAna	303.3 (80.8)	404.6	73.0	0.49	726.7/1749.0
BAnana	257.2 (65.5)	409.2	65.6	0.46	751.2/2111.6
BUnny	250.3 (69.1)	414.0	62.1	0.69	435.5/2597.8
buNNY	260.2 (66.2)	358.8	70.1	0.89	412.9/2241.8
Pitch only–first syllable					
baNAna	200.8 (2.9)	209.4	70.6	0.49	891.9/1606.2
BAnana	387.4 (29.4)	420.5	72.1	0.49	862.8/1668.4
BUnny	368.4 (20.7)	394.2	69.8	0.42	987.4/1749.2
buNNY	200.4 (4.9)	215.2	70.0	0.43	798.0/1741.3
Pitch only–second syllable					
baNAna	332.6 (71.2)	395.3	69.9	0.52	850.6/1779.4
BAnana	222.1 (30.9)	317.3	69.8	0.52	818.2/2008.2
BUnny	233.1 (58.9)	394.1	68.4	0.75	511.2/2658.7
buNNY	292.7 (72.2)	387.3	67.6	0.74	464.2/2738.6
"Where is the BUnny? That's pretty."

Fig. 2. Example photographs used in both experiments along with example sentences.

by Sarah Creel. The result of this processing was information, for each trial, about the proportion of time each participant was fixating each location (target, distracter, other, offscreen, or lost data) during each 50-ms time bin.

Results and discussion

Fig. 3 plots adults' fixations of the target picture over time in both the convergent-cues and pitch-only conditions. Time on the *x* axis is displayed relative to target word onset. Gaze proportions in Fig. 3 are averaged within each 50-ms time bin, and numbers on the *x* axis represent the end of each time bin. Zero (0) on the *x* axis, thus, represents the time bin from 50 to 0 ms before the onset of the target word. The ambiguous region, "bun," ended at 610 ms for all stimuli (the first syllable, "bu…", ended at roughly 450 ms; see Table 1 for details). By considering the time course of participants' responses, we can get a sense of how they integrated the information about first-syllable stress—which in "mis-stressed" trials should mislead them to fixate the distracter object—with the later-arriving segmental information starting in the second syllable (the "nny" in *bunny* vs. the "nana" in *banana*).

Convergent-cues condition

Gaze responses indicated that adults were very sensitive to convergent misstressings of the words, as expected. For both words, adults identified the target picture straightforwardly when stress cues were consistent with the word ("BUnny" or "baNAna"), but their target fixation dipped substantially

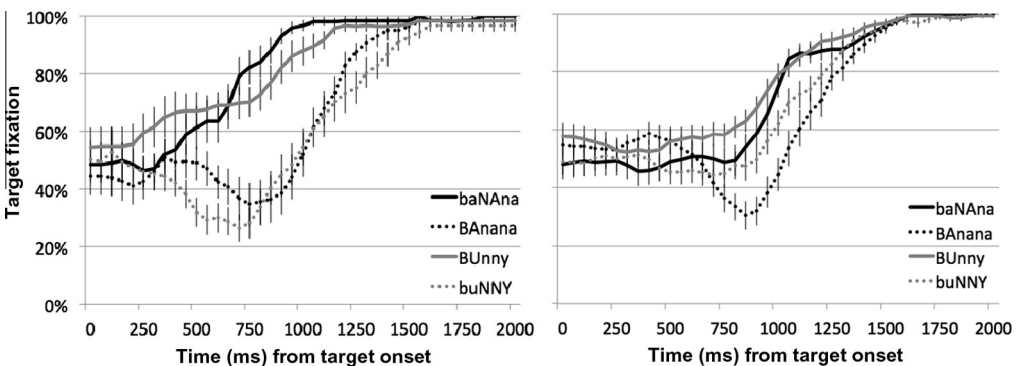

Fig. 3. Adults' target fixation over time in response to convergent stress cues (left) and isolated pitch cues (right).

when stress was inconsistent ("buNNY" or "BAnana") before increasing to asymptote at 100% once segmental information was unambiguous (i.e., once adults had heard either the "nny" in bunny or the "nana" in banana). The effect of misstressing occurred faster for bunny than for banana (the "BUnny" and "buNNY" lines diverge sooner than the two *banana* lines).

Pitch-only condition

Looking-time measures revealed less sensitivity to misstressings of the pitch cue alone than of all four convergent cues. Nevertheless, for both words, target fixation was higher in correctly stressed trials than in misstressed trials. When adults heard "BAnana" with a pitch pattern appropriate for *bunny,* their target fixation dipped as they looked over at the bunny picture, just as we found for convergent stress cues. When adults heard "buNNY" with a pitch pattern appropriate for *banana,* their response was uncertain (target fixation revealed a middling response, lower than when pitch signaled *bunny* but still not so much as to favor *banana*). This could be because for adults pitch is asymmetric; high pitch definitely indicates a stressed syllable, whereas the absence of high pitch does not clearly indicate an unstressed syllable. A plausible additional explanation is that the pitch cue was competing with a long syllable duration, so adults were responding to cue *conflict* with uncertainty (whereas for BUnny the pitch and syllable duration were convergent cues indicating a stressed syllable). Either way, the pitch manipulation affected listeners' interpretation of both words by drawing fixations in the predicted direction, although not always to the degree one might expect if pitch were the only cue to stress that listeners were accustomed to exploiting.

To compute inferential statistics on the looking-time data, we first averaged target-fixation proportions across the time window of 200 to 2000 ms post-noun onset. The start of this window is the earliest adults can initiate an eye-movement response (Hallett, 1986). In Experiment 2, the time window began slightly later, at 350 ms, based on prior findings that before 367 ms children are unlikely to be responding to the target word (Fernald, Pinto, Swingley, Weinberg, & McRoberts, 1998; Swingley & Aslin, 2000; we used 350 ms here because data were binned in 50-ms chunks). The end of the window was chosen because after 2000 ms both adults and children have usually finished identifying and fixating the target picture. Table 2 summarizes mean target fixations for this time window. We also calculated participants' asymptotic performance (the window of 2000–3000 ms) to estimate their ultimate choice of target picture. Among adults, performance in this window was uniformly high—more than 97% even on the misstressed naturalistic-stress trials. Children in Experiment 2 varied more than adults on this measure.

We next conducted a by-participants analysis of variance (ANOVA) in which the dependent variable was target-fixation proportion and the predictors were the word ("bunny" or "banana"), the cue type (convergent cues or pitch only), the pronunciation (correct or misstressed), and their interactions. Pronunciation exerted a significant effect on target fixation, $F(1,46) = 41.6$, $p < .001$, which was higher in response to correctly stressed words ($M = 80.0\%$, $SD = 8.6$) than in response to misstressed words ($M = 69.8\%$, $SD = 9.1$) with a large effect size (paired Cohen's $d = 0.84$). There was also a significant interaction between pronunciation and cue type, $F(1,46) = 12.6$, $p < .001$. In follow-up t tests, convergent-cues and pitch-only participants did not differ significantly in target fixation on

Table 2

Mean target fixation (and standard deviations) in the two conditions—convergent (all) cues and pitch cue only—for adults (Experiment 1) and children (Experiment 2).

Word	Correctly stressed			Misstressed		
	BUnny	baNAna	All	buNNY	BAnana	All
Adults (Experiment 1)						
All cues	85.4 (12.0)	86.1 (9.1)	85.8 (6.6)	65.7 (9.9)	69.8 (13.3)	67.8 (8.0)
Pitch	78.9 (11.0)	75.3 (13.3)	77.1 (8.1)	72.3 (12.8)	69.5 (12.9)	70.8 (9.6)
Children (Experiment 2)						
All cues	74.5 (18.8)	64.4 (17.4)	69.5 (13.0)	54.0 (19.8)	53.4 (17.7)	53.6 (13.5)
Pitch	64.3 (22.4)	50.1 (19.7)	57.1 (13.5)	59.6 (26.5)	50.7 (21.2)	55.2 (14.2)

Note: Values in the table are percentages.

misstressed trials (convergent cues: 67.7%; pitch only: 70.9%), but convergent-cues participants showed significantly higher target fixation in *correctly stressed* trials (convergent cues: 85.8%; pitch only: 77.1%), unpaired $t(36.3) = 4.0$, $p < .001$, with a large effect size (pooled Cohen's $d = 1.14$). Thus, when all cues indicated that the correct syllable was stressed (i.e., on correctly stressed trials in the convergent-cues condition), participants responded quickly and accurately. However, when cues were more mixed in pitch-only "baNAna" and "BUnny" trials—where amplitude, duration, and vowel quality cues had been neutralized—participants were relatively slow in identifying the target words.

In sum, adults were sensitive to mispronunciations of the pitch cue to stress for both "bunny" and "banana," although they responded more strongly to convergent stress cues. In Experiment 2, we tested preschool-age children's ability to exploit convergent versus pitch-only cues to the location of stress.

Experiment 2

Method

Participants

Children between 2.5 and 5 years of age were tested. A total of 206 children were included in the analyses: 100 in the *convergent-cues* condition and 106 in the *pitch-only* condition (102 girls and 104 boys, mean age = 4 years 7 days, SD = 1 year 27 days); the sample included 50 2-year-olds, 52 3-year-olds, 52 4-year-olds, and 52 5-year-olds, roughly equally distributed across the two conditions). Children were recruited via letters sent to parent addresses from a commercial database and by word of mouth. An additional 38 children were excluded from the analysis for inattentiveness ($n = 19$), because they were hearing a language other than English at home more than 30% of the time or were exposed to a tone language (which could increase sensitivity to the pitch cue to stress; $n = 10$), for reported language or cognitive delays ($n = 4$), for talking/screaming over the auditory stimuli ($n = 2$), because of distracting noise in the room (from a younger sibling; $n = 1$), and because parents reported that their children did not understand either the word "bunny" or "banana" ($n = 2$). Children were deemed to be inattentive if, in more than half (2) of the trials in each trial type (e.g., "BUnny" or "buNNY"), they failed to fixate the pictures for at least 300 ms during the analyzed time window (350–2000 ms after noun onset).

Apparatus and procedure

The procedure was very similar to that used with adults. The differences were that some children sat on a parent's lap and the experiment was only approximately 5 min long, containing 32 trials and the attention-getting videos.

Results and discussion

We tested children across a wide age range (2.5–5 years) so as to track the developmental timing of any relevant changes in phonetic interpretation over this period. In fact, in an analysis of covariance (ANCOVA) described below, children's performance within the analyzed time window (350–2000 ms after noun onset) did not show important developmental change with regard to the variables of interest (number of cues to stress and whether the word was correctly stressed vs. misstressed), although children as a group did respond differently from adults. Still, some age differences were noticeable in our measure of asymptotic performance (the analysis window 2000–3000 ms after the target word's onset). In experimental trials overall, 4- and 5-year-olds reached an asymptote of 76.5% target fixation (SD = 15.6), whereas 2.5- and 3-year-olds reached 70.1% (SD = 14.7). Thus, to further investigate effects of age on performance, we included ANCOVAs investigating children's responses both in the primary analysis window (350–2000 ms) and in this asymptotic window (2000–3000 ms).

Convergent stress condition

We predicted that children, like adults, would be sensitive to misstressings of "bunny" and "banana" when all four cues were allowed to covary in the typical English fashion, although this ability

might vary across age (see ANCOVAs below). Plots of children's target fixation over time (Fig. 4, left) indicate that, indeed, children fixated the target picture more when the word was correctly stressed than when it was misstressed. This was true for both words in spite of an overall preference, beginning before target word onset, to fixate the bunny picture. Children responded slightly earlier to misstressing of *bunny* than misstressing of *banana,* as adults had done in Experiment 1.

Pitch-only condition

Two aspects of the pitch-only responses (Fig. 4, right) are most salient. First, children again showed a bias, which preceded target word onset, to fixate the bunny picture. Second, children showed little sensitivity to the pitch cues. They appeared to detect the anomalous pitch in "bunny" late in the time window; target fixation in response to the correctly stressed version of "bunny" began to exceed that in response to the misstressed version around 1000 ms post–target onset. However, this effect was numerically small and did not increase with age, and there was no such effect for "banana."

To evaluate whether children's age affected their sensitivity to mispronunciations of convergent versus pitch cues, we conducted a by-participants ANCOVA in which the dependent variable was target fixation proportion, the continuous predictor was age, and the categorical predictors were the word ("bunny" or "banana"), the cue type (convergent cues or pitch only), and the pronunciation (correct or misstressed). Interactions of all predictors were also included.

There was a significant main effect of cue type, $F(1, 202) = 15.7$, $p < .001$, reflecting higher overall target fixation in response to convergent cues ($M = 61.5\%$, $SD = 9.5$) than in response to the isolated pitch cues ($M = 56.1\%$, $SD = 10.1$) with a medium effect size (pooled Cohen's $d = 0.54$). Pronunciation also exerted a significant effect on target fixation, $F(1,202) = 46.2$, $p < .001$, which was higher in response to correctly stressed words ($M = 63.1\%$, $SD = 14.6$) than in response to misstressed words ($M = 54.4\%$, $SD = 13.9$) with a small to medium effect size (paired $d = 0.43$). Cue type interacted significantly with pronunciation, $F(1,202) = 28.7$, $p < .001$. Follow-up t tests revealed that mispronunciations decreased children's fixation of the target picture in the convergent-cues condition, paired $t(99) = 8.6$, $p < .001$, with a large effect size (paired $d = 0.86$), but not in the pitch-only condition (see Table 2 for means). As with adults, the effect of cue type appeared only in *correctly stressed* trials, unpaired $t(204.0) = 6.7$, $p < .001$, with a large effect size (pooled $d = 0.94$); the two participant groups did not differ in misstressed trials. There was also a significant effect of target word, $F(1, 202) = 20.2$, $p < 001$, with a small effect size (paired $d = 0.31$), reflecting children's overall preference for *bunny* ($M = 63.0\%$, $SD = 18.1$) over *banana* ($M = 54.5\%$, $SD = 16.1$). Pronunciation also interacted with target word, $F(1, 202) = 11.3$, $p < .001$, reflecting a larger mispronunciation effect for "bunny" than for "banana" (see Table 2 for means), but the mispronunciation effect was significant for both words. For *bunny*:

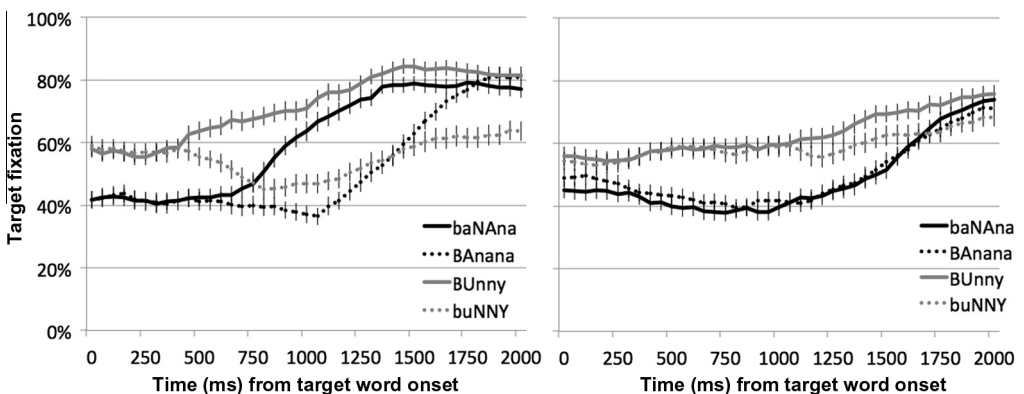

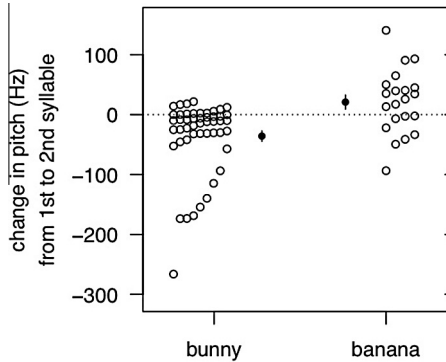

Fig. 4. Children's fixation of the target picture over time in response to convergent stress cues (left) and isolated pitch cues (right).

Fig. 5. Change in pitch (Hz) from the first syllable to the second syllable for tokens of *bunny* and *banana* in the corpus analysis. Means and standard errors are indicated with filled circles and vertical lines.

paired $t(205) = 6.6$, $p < .001$, with a medium effect size (paired $d = 0.55$). For *banana*: paired $t(205) = 3.1$, $p < .005$, with a small effect size (paired $d = 0.25$).

Children's age was not correlated with their target-fixation proportions during the primary time window. This is somewhat surprising because children generally improve with age in picture-fixation assessments of word recognition (Fernald, Perfors, & Marchman, 2006; Fernald et al., 1998), and speed increases between kindergarten and adulthood (Sekerina & Brooks, 2007). This prompted our analysis of asymptotic performance in a later time window, where we evaluated whether children would show some developmental improvement in performance independent of their attempts to interpret the first syllable in our word pair. To this end, we conducted a second ANCOVA in which asymptotic performance was the dependent variable (defined as target-fixation proportions averaged over 2000–3000 ms after noun onset). As before, the predictors were the word ("bunny" or "banana"), the cue type (convergent cues or pitch only), and the pronunciation (correct or misstressed). In this ANCOVA, we did find a main effect of the continuous variable age, $F(1, 202) = 8.4$, $p < .005$, although it did not interact with our other factors of interest (all $ps > .29$). A Pearson's correlation test indicated that age was positively correlated with overall asymptotic performance ($r = .21$, $p < .005$).[2]

In sum, both children and adults exploited convergent stress cues to identify familiar words. Both age groups responded more strongly to convergent misstressings than to pitch-only mispronunciations, and in both cases this difference appeared in correctly stressed trials. However, whereas adults as a group used pitch to guide their identification of which word they were hearing, children did not. There was no difference across age in children's responses to misstressings of either convergent cues or pitch alone, although age was correlated with overall asymptotic performance in the task.

One possible reason why children might have been unable to exploit the pitch cues could be that in fact, contrary to our assumptions, pitch is an unreliable cue to stress in child-directed speech. To confirm the utility of pitch in contexts like those we tested here, we examined pitch patterns in *bunny* and *banana* in the Providence corpus of parental speech (Demuth, Culbertson, & Alter, 2006) available in the CHILDES database (MacWhinney, 2000). Because of strong influences of context on pitch realizations, we restricted the analysis to words in utterance-final position and to words not in yes/no questions (for words in isolation, yes/no questions were inferred using utterance prosody).

---

[2] The asymptotic ANCOVA also revealed a main effect of pronunciation, $F(1, 202) = 14.2$, $p < .001$, with a small effect size (paired $d = 0.21$), indicating higher asymptotic target fixation in normal-stress trials ($M = 75.5\%$, $SD = 18.5$) than in misstressed trials ($M = 71.2\%$, $SD = 19.0$). Pronunciation also interacted with cue type, $F(1, 202) = 6.2$, $p < .05$. As before, mispronunciations decreased children's fixation of the target picture in the convergent-cues condition, paired $t(99) = 3.19$, $p < .005$, with a small effect size ($d = 0.32$; correctly stressed: $M = 77.4\%$, $SD = 18.7$; misstressed: $M = 70.6\%$, $SD = 18.8$), but not in the pitch-only condition (correctly stressed: $M = 73.8\%$, $SD = 18.2$; misstressed: $M = 71.7\%$, $SD = 19.4$). Finally, there was a three-way interaction among word, condition, and pronunciation, $F(1, 202) = 7.4$, $p < .01$, indicating that the effect of mispronunciations in the convergent-cues condition was significant only for *bunny* trials, $t(99) = 4.85$, $p < .001$, with a medium effect size (paired $d = 0.61$).

In total, 21 tokens of *banana/bananas* and 49 tokens of *bunny/bunnies* were included in the corpus analysis. Each token was hand-segmented into syllables using Praat (Boersma & Weenink, 2008), and a Praat script calculated pitch means, amplitude means, and durations for the first and second syllables. For each of these acoustic dimensions, a difference score was calculated to reflect the first-syllable value minus the second-syllable value. Analyses showed that pitch tended to fall from the first syllable of *bunny* to the second and to rise from the first syllable of *banana* to the second (Fig. 5).

Linear mixed-effects logistic regression models were used to assess the power of pitch, amplitude, and duration to predict whether the word was *bunny* or *banana*. Because there were five mother–child pairs in the corpus, mother–child pair was included as a random effect and the full model included pitch difference, duration difference, and amplitude difference as fixed effects. In the full model, only pitch difference significantly predicted the word ($z = 2.72$, $p < .01$). The full model's performance was only marginally better than a model that included only pitch difference as a fixed effect, $\chi^2(2) = 4.83$, $p = .089$ (full model comparison details are available from the authors). Thus, in this sample of child-directed speech from five American mothers, pitch appeared to be a better predictor of word stress than either amplitude or duration, at least for *bunny* and *banana* realized in salient prosodic contexts similar to those of our test sentences. This does not imply that pitch as a cue should be easy to learn, but it suggests that pitch could be a useful cue for differentiating iambic and trochaic words.

General discussion

The two experiments described here showed differences between preschoolers and adults in their ability to exploit an isolated cue to lexical stress. Across the two experiments, we found that both adults and children (2.5- to 5-year-olds) exploited convergent cues to lexical stress in recognizing *bunny* and *banana*. Participants took longer to identify the target picture when the stress of the first syllable violated their expectations (as in "buNNY" and "BAnana") than when stress matched their expectations (as in "BUnny" and "baNAna"). The fact that even 2.5-year-old children exploited lexical stress when it was indicated by all four convergent cues is noteworthy and convergent with other recent findings by Curtin (2009, 2010) and with the predictions of Peperkamp (2004). We might have predicted a more protracted acquisition pattern for lexical stress in English given its low functional load relative to lexical stress in other languages. Whereas a Spanish-learning preschooler might know "PApa" (potato) and "paPÁ" (dad), an English-learning preschooler is less likely to know minimal pairs such as "REcord" (the noun) versus "reCORD" (the verb). Lexical stress in English is also limited in its scope in that it cannot minimally contrast monosyllabic words as lexical tone does (Beckman & Edwards, 1994). Thus, it is perhaps surprising that by 2.5 years of age, English learners can use lexical stress as efficiently as 5-year-olds to predict the word they are hearing, differentiating between pseudo-minimal pairs such as "bunny" and "banana."

Adults were able to exploit pitch cues presented in the presence of neutralized (or at least ambiguous) duration, amplitude, and vowel quality cues to recognize "bunny" and "banana," but children were not. Although age was positively correlated with asymptotic performance in the task, it did not predict responsiveness to mispronunciations of stress.

There are three plausible—and not mutually exclusive—explanations for children's insensitivity to isolated pitch cues in this task. The first possibility is that children's cue weighting or cue integration is different from that of adults. It could be that children weight other cues (duration, intensity, or vowel quality) more strongly than pitch. Reliance on other cues could come about because the pitch cue to lexical stress interacts with sentence intonation, leading to variability in its realization (it has a high pitch target in "neutral" contexts such as statements but has a low target in yes/no questions). The multiple functions of pitch in English (e.g., marking focus, conveying the speaker's emotions) also lead to ambiguity in how a pitch peak should be attributed. Both of these factors likely reduce the reliability of the pitch cue.

A second possible reason why children did not exploit pitch cues to stress is that the manipulation of the pitch cue in the presence of static amplitude, duration, and vowel-quality cues introduced unavoidable cue conflict that might have posed particular difficulty for children. We attempted to remove the information value of the other three stress cues by recording "neutrally" stressed versions of

"bunny" and "banana" and then superimposing the pitch contour from first- and second-syllable-stressed versions of each word onto the neutral token. However, there is no such thing as neutral stress in English, meaning that some amount of bias toward trochaic or iambic stress could not be avoided. In our stimuli, words were produced with a slow, exaggerated speech style, making it likely that the first syllable of the word (putatively the most important for recognition because listeners process the words incrementally; Creel, Aslin, & Tanenhaus, 2006; Swingley, 2009) had duration and vowel quality cues more consistent with its being stressed than with its being unstressed (amplitude was controlled). Thus, when the pitch cue indicated second-syllable stress (in "baNAna" and "buNNY"), children might have struggled to resolve the conflict between the pitch cue and duration and vowel quality. By contrast, adults overcame this cue conflict more easily to successfully exploit the locally informative pitch cues.

Our results suggest that both explanations might be relevant in describing children's behavior. Children's pitch-mispronunciation effects for both words were weak to nonexistent, and target fixation was low overall relative to the convergent-cues condition (see Fig. 4 and Table 2), suggesting that children struggled to access the pitch cue in general even when it converged with the other cues—when it indicated first-syllable stress. In other words, they did not reliably fixate the *bunny* more in response to the initial portions of "BUnny" and "BAnana" (the latter would have shown up as reduced target fixation relative to "baNAna") than in response to "buNNY" and "baNAna." However, target fixation did tend to be higher for "BUnny" than for "buNNY"; this might reflect the fact that "BUnny" was the most highly convergent of all words, with all four cues to stress and the segmental content of the entire word pointing to *bunny*, whereas "BAnana," although it had convergent stress cues in the first syllable (pointing to *bunny*), had divergent segments in the second and third syllables ("nana"). Children's modest success in "BUnny" trials relative to the other three target words suggests that the task might have been difficult because of additive effects of (a) the subtlety of the pitch cue and (b) the conflict between it and the other cues to stress (which again was unavoidable given that "neutral" stress does not exist, so that information from the other cues could be weakened and made invariant but not entirely extinguished).

A third and final difference between adults and children might be adults' greater ability to flexibly shift their weights of different cues to adapt to the particular context. In the pitch-only condition, pitch was the most reliable cue in the local context in the sense that it was varying in the presence of static amplitude, duration, and vowel-quality cues. Of course, it was *unreliable* in the sense that half of the time it indicated the wrong word (in "buNNY" and "BAnana"), but adults may have shifted their cue weightings to attend primarily to pitch, the cue that was varying across sentences. Flexibly shifting cue weights is crucial for identifying linguistic categories in noise and across different contexts and has been demonstrated to develop over a protracted time course (Cohn, 2011; Hazan & Barrett, 2000; Nittrouer et al., 2000), which could explain why even 5-year-olds did not exploit the isolated pitch cue in our task. Of course, even adults performed best when all stress cues converged as in natural speech, but, crucially, in the pitch-only condition they were able to capitalize on the locally informative cue.

Despite evidence that young infants are highly sensitive to pitch, and despite the early acquisition of consonant and vowel categories, we found that correct *interpretation* of discriminable pitch exhibits a protracted learning course. Children learn to rule out pitch as lexically contrastive in English by 24 months of age (Singh et al., 2014; Quam & Swingley, 2010), but they seem to take longer to learn to exploit pitch when it *is* relevant in English as a component of ensembles of phonetic cues to meaning. Children do not exploit pitch cues to emotions until around 4 years of age (Quam & Swingley, 2012), and the current study indicates that they struggle to exploit pitch cues to lexical stress even at 5 years of age.

Based on these data alone, we cannot conclusively identify the cause of children's failure to exploit isolated pitch cues to stress. We have identified three possible—not mutually exclusive—explanations: differences in baseline cue-weighting strategies, inability to resolve conflict between the pitch cue and the other three cues in the stimuli, and inability to flexibly shift cue weights to capitalize on the locally informative cue.

The late developmental time course found here for exploiting pitch cues to stress stands in contrast to the evidence that young infants are highly sensitive to pitch, that infants learn consonant and vowel categories by 12 months of age, and that children of the same age do exploit convergent stress cues. It

emphasizes, however, that detecting patterns of sounds in language (consonants, vowels, and prosodic structure) is just a first step in phonological development. Children also must learn how their language weaves together these patterns of sound to convey meaning across several levels of linguistic analysis. In learning to properly attribute acoustic variation, children must cope with ambiguity in the assignment of acoustic cues to categories (e.g., whether a pitch peak indicates a stressed syllable, a focused word, or the speaker's excitement (cf. Dietrich et al., 2007) and variability in the realization of cues introduced by linguistic context, environmental noise, and other factors. Evidence from these experiments and others (e.g., Hazan & Barrett, 2000; Nittrouer et al., 2000; Quam & Swingley, 2012) suggests that this learning process continues well into childhood.
